Tamarin: Concolic Disequivalence for MIPS

Abel Nieto

University of Waterloo
anietoro@uwaterloo.ca

Abstract. Given two MIPS programs, when are they equivalent? At first glance, this is tricky to define, because of the unstructured nature of assembly code. We propose the use of alternating concolic execution to detect whether two programs are disequivalent. We have implemented our approach in a tool called Tamarin, which includes a MIPS emulator instrumented to record symbolic traces, as well as a concolic execution engine that integrates with the Z3 solver. We show that Tamarin is able to reason about program disequivalence in a number of scenarios, without any a-priori knowledge about the MIPS programs under consideration.

1 Introduction

We are staring at two opaque black boxes laying at our feet. Each box has a narrow slot through which we can place items in the box, but we cannot quite see what is inside. They look approximately like this:

We know each box contains an animal, but we do not know which specific animal is in each one. We would like to find out if both boxes contain the same species of animal. Our solution is simple: we take two carrots, and drop one in each box through the slots.

After a while, a chewing sound emerges from the boxes. We peer into them and, indeed, it looks like the carrots were successfully eaten. Triumphantly, we declare that the boxes contain the same species of animal. The truth is altogether different:

The boxes are assembly programs. The animals are the functions those programs compute. The carrot is unit testing. The task was to determine whether the programs were equivalent. And we failed at it. In this paper, we show a technique that is better than a carrot.

2 Program Equivalence for MIPS

Let us set up the problem a bit more formally. Consider the set P of MIPS-assembly programs that satisfy two restrictions: they take as inputs only the values of registers

$1 and $2, and when they stop executing we define their output to be (exclusively) the value of $3. Other side effects, such as printing values to the screen, or system calls, are disallowed.

We can now define a relation $\mathsf{equiv} \subseteq P \times P$ (and its complement, $\not{\mathsf{equiv}}$) of equivalent programs. Given $P_1, P_2 \in P$, we say that P_1 equiv P_2 (read "P_1 is equivalent to P_2") if, for all inputs $1 and $2, one of the following holds:

- Both P_1 and P_2 fail during execution (for example, due to a divide-by-zero error).
- P_1 and P_2 stop with the same output in $3.

For example, the two programs in Figure 1 are equivalent.

```
# P_1
add $3, $1, $2
```

```
# P_2
add $4, $1, $1
lis $5
42
sw $4, 0, $5
add $3, $1, $2
```

Fig. 1. P_1 equiv P_2

Notice that P_1 equiv P_2 even though P_2 modifies the contents of the memory and an additional register ($4), because:

- Both P_1 and P_2 terminate without errors.
- The value of $3 will be the same when they do so.

Unfortunately, even though equiv captures an already-simplified notion of equivalence[1], a decision procedure for it does not exist, due to Rice's theorem.

To get decidability back, we define a new class of relations $\mathsf{equiv}_S \subseteq P \times P$ (whose complement is $\not{\mathsf{equiv}}_S$). We say that P_1 equiv_S P_2 (read "P_1 is S-equivalent to P_2") if, for all inputs, one of the following holds:

- Either P_1 or P_2 does not stop within S steps (we can think of each CPU cycle as one step).
- Both P_1 and P_2 fail.
- Both P_1 and P_2 stop with the same output.

The equiv_S relation captures the notion that we cannot tell P_1 and P_2 apart by running them for at most S steps. Figure 2 shows an example of two programs that are S-equivalent for $S = 10$, but not equivalent. This is the case because P_2 loops while the counter is less than 42, so with 10 steps in our "budget" we will have to stop P_2 before the loop is over and we can observe the different result.

Given a fixed S, the equiv_S relation is decidable because there is a finite number of inputs to try, and for each input we only need to run the programs a finite number of steps.

[1] For example, equiv has a very narrow notion of output that excludes side effects.

```
# P_1
add $3, $1, $2
```

```
# P_2
  add $4, $0, 1  # counter
  add $5, $0, 42 # upper bound
loop:
  slt $6, $4, $5
  beq $6, $0, end
  add $4, $4, 1
  beq $0, $0, loop
end:
  add $3, $1, $1
```

Fig. 2. P_1 equiv_{10} P_2, but P_1 ~~equiv~~ P_2

.

We already saw that equivalence not always implies S-equivalence. However, the converse always holds. The following lemma shows that equiv_S over-approximates equiv.

Lemma 1. $\forall S, P_1, P_2,\ P_1\ \mathit{equiv}\ P_2 \implies P_1\ \mathit{equiv}_S\ P_2$.

Proof. Let P_1 equiv P_2. Consider two arbitrary inputs x and y. Then we have one of two cases:

- Either P_1 or P_2 (or both) do not stop within S steps when run on x and y. This is the first case in the definition of equiv_S.
- Both P_1 and P_2 stop within S steps. Then because they are equivalent, we know that they either fail with an error, or both stop with the same output. These are the second and third cases in the definition of equiv_S.

Therefore, we must have P_1 equiv_S P_2.

Corollary 1. P_1 ~~equiv_S~~ $P_2 \implies P_1$ ~~equiv~~ P_2.

Proof. This is just the contrapositive of Lemma 1.

Corollary 1 can be used to argue the soundness (with respect to ~~equiv~~) of any decision procedure that under-approximates ~~equiv_S~~. In the next section we will show one such under-approximation based on concolic execution.

3 Concolic Disequivalence

We know from Corollary 1 that any relation that under-approximates ~~equiv_S~~ is sound. Figure 3 shows why we want an under-approximation: efficiency. ~~equiv~~ captures the class of programs that are disequivalent, but is undecidable. ~~equiv_S~~ is decidable, but likely cannot be computed efficiently. Therefore, we look for a subset of ~~equiv_S~~ (an under-approximation) that can be efficiently computed.

To fill the missing relation in Figure 3 we propose concolic disequivalence. Abstractly, concolic disequivalence is a function $\mathsf{compare}(P_1, P_2, S)$ that takes as inputs two MIPS programs and returns one of two answers:

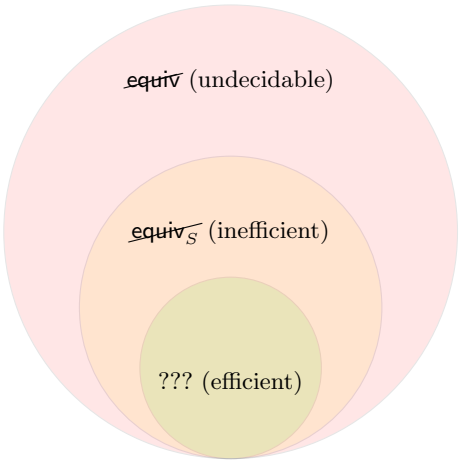

Fig. 3. Hierarchy of disequivalence relations

– "disequivalent", in which case $P_1 \not{\text{equiv}}_S P_2$.
– "possibly equivalent", meaning that P_1 and P_2 might or might not be S-equivalent.

Figure 3 shows pseudocode for compare. The algorithm alternately executes P_1 and P_2. At every step, one of the programs is labelled as the "driver" and the other one as the "verifier". The driver program is then concolically executed, yielding a set of inputs that exercise a new program path (of the driver). The inputs can then be fed to the verifier, and the results of both driver and verifier compared. If the results are different, then we know P_1 and P_2 are disequivalent. Otherwise, the driver becomes the verifier, and vice-versa. Eventually, we will traverse all explorable paths, at which point P_1 and P_2 can be declared possibly equivalent.

We now give an example of how compare operates. Consider the sample programs below:

```
# P_1
  bne $1, 42, end
  add $3, $3, $0
end:
  add $3, $1, $2
```

```
# P_2
  add $3, $1, $2
  bne $2, 100, end
  add $3, $3, $2
end:
```

Figure 5 summarizes the state of the algorithm as it compares P_1 and P_2. First, notice how the driver and verifier roles flip between P_1 and P_2 in consecutive runs. Every row indicates the input values, as well as the outputs R_D and R_V of the driver and verifier, respectively. At every run, we also record the path taken by the driver. Path conditions are negated to make sure we explore new paths in every iteration. In the fourth iteration, we can see that compare finds that the input pair $\$1 = 1, \$2 = 100$ leads to different outputs in the driver and verifier. At this point, P_1 and P_2 are declared as disequivalent.

Notice that in order to uncover the different, it is necessary to concolically explore the paths in both P_1 and P_2, and not only of P_1. In Figure 5, runs 1 and 3 explore

```
function COMPARE(P1, P2, S)
    b ← true
    while either P1 or P2 has unexplored paths do
        if b then                                          ▷ Select driver and verifier
            D ← P1
            V ← P2
        else
            D ← P2
            V ← P1
        end if
        if D has unexplored paths then
            I ← new inputs that exercise an unexplored path
            R1 ← run(P1, I, S)
            R2 ← run(P2, I, S)
            if both P1 and P2 stopped then
                if both P1 and P2 stopped with an error then
                                                           ▷ do nothing
                else if either P1 or P2 stopped with an error then
                    return "disequivalent"
                else
                    if R1 ≠ R2 then
                        return "disequivalent"
                    end if
                end if
            end if
            mark the path discovered by I as explored
            b ← ¬b
        end if
    end while
    return "possibly equivalent"
end function
```

Fig. 4. Concolic disequivalence algorithm

both branches of the conditional jump in P_1, but they exercise the same path in P_2. Only after we also execute P_2 do we find a counterexample to equivalence.

Run	Driver	Verifier	$1	$2	Path	R_D	R_V
1	P_1	P_2	1	1	$\$1 \neq 42$	2	2
2	P_2	P_1	1	1	$\$2 \neq 100$	2	2
3	P_1	P_2	42	1	$\$1 = 42$	2	2
4	P_2	P_1	1	100	$\$2 = 100$	201	2

Fig. 5. A sample execution of compare

4 Tamarin

Tamarin[2] is a Scala implementation of the compare algorithm from Section 3. We first give an overview of the major modules in Tamarin, shown in Figure 6, and then describe them in more detail in subsequent sections:

- Concolic is the entry point to Tamarin. It implements the top-level loop that visits unexplored paths, alternating between the two programs being compared. Concolic uses the other modules as helpers (in Figure 6, requests made by a module appear as solid lines, and responses to prior requests are shown with dashed lines).
- CPU is a MIPS emulator that is instrumented to record symbolic traces containing path conditions, which can later be negated to explore new paths.
- Trace consumes raw traces coming from CPU and transforms them in multiple ways so that they can be handed over to the Z3 solver.
- Query translates (modified) CPU traces into equivalent logical formulae. The formulae are then solved by the Z3 solver, producing new inputs that, if fed to the program under test, will lead to traversing unexplored paths.
- Z3 is an SMT solver developed at Microsoft [De Moura and Bjørner, 2008]. We use it as black box for solving queries, over the theories of bitvectors and arrays, that result from program traces.

4.1 Trace Collection

The CPU module is in charge of running MIPS programs and collecting symbolic traces from executions. It is based on the MIPS emulator written by Ondřej Lhoták for CS241E at the University of Waterloo [Lhotak,].

The interface to the module consists of a single function:

```
def run(prog: Seq[Word], r1: Word, r2: Word, fuel: Long): RunRes
```

[2] Tamarins are small-sized monkeys from Central and South America. They are related to marmosets, which are also New World monkeys, and less-importantly give name to the black-box submission and testing server in use at the University of Waterloo as of Fall 2017 [Spacco et al., 2006].

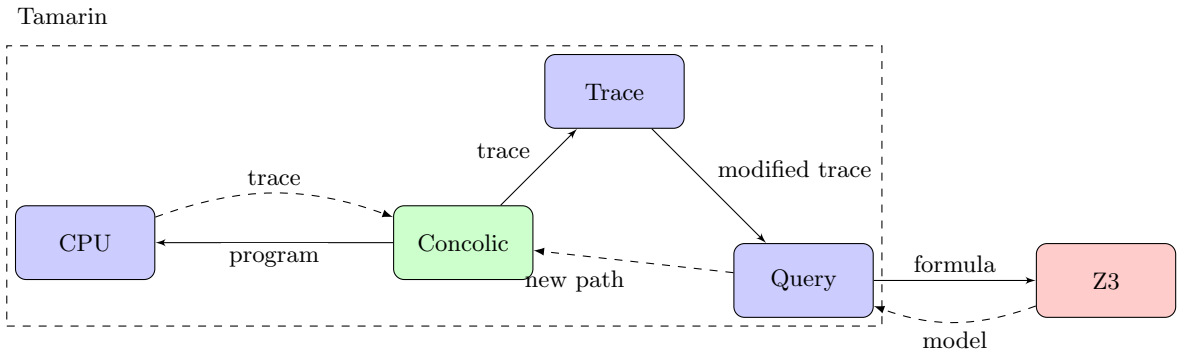

Fig. 6. Overview of Tamarin's modules

The run function takes as input a program represented as as sequence of words, the values of registers $1 and $2 (the inputs to the program) and a fuel value (explained below).

The output is an algebraic data type RunRes that can take one of three forms:

```
trait RunRes
case class Done(state: State, trace: Trace) extends RunRes
case class NotDone(trace: Trace) extends RunRes
case class Error(ex: RuntimeException) extends RunRes
```

- If the program executes without error, then Done(state, trace) is returned. state is the state of the CPU after execution, including the contents of memory (which are ignored) and of register $3, the output register. trace is the symbolic trace captured during the program's execution, and is described below.
- If the program ran for more than fuel CPU cycles without stopping, then the result is NotDone(trace). Notice that even though the program did not stop we can still return a trace recording the execution right until the moment we stopped it. The fuel argument to run plays the same role as the S argument in Figure 3.
- Finally, if there was an error during program execution (for example, an attempted division-by-zero), then we return Error.

Notice that due to fuel parameter and error boxing, the augmented emulator in Tamarin, unlike a vanilla MIPS emulator, is "hardened" in the sense that it can execute MIPS programs that do not stop (the emulator itself will stop) or throw errors (will be catched at the top level by the emulator).

While the emulator is executing a program, it also records a symbolic trace of (most of) the executed instructions. We support a subset of the MIPS instruction set, containing 18 instruction types [Staff, 2017]. Notably, unlike in full MIPS, there are no system calls in our supported subset.

The fetch-decode-execute cycle in our emulator is modified to record a symbolic representation of each instruction as it is executed (Figure 7). The symbolic instructions are then stored in a trace. There are two types of instructions in a trace: assignments and path conditions.

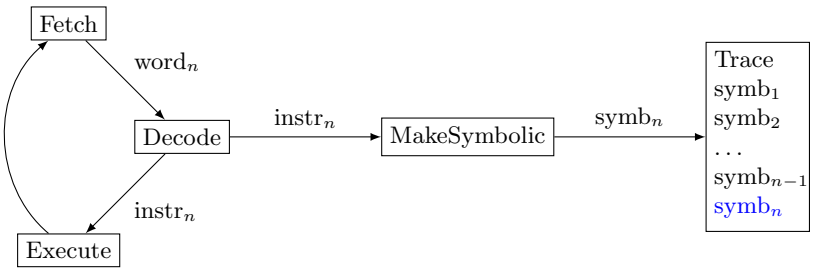

Fig. 7. Instrumented CPU that records symbolic traces

- Assignments are instructions that mutate the CPU state, but do not affect the control flow. The symbolic form of most assignments is very similar to the concrete instruction that is executed. For example, the symbolic representation of the instruction `add $3, $1, $2` is $r_3 \leftarrow r_1 + r_2$.
- Path conditions are instructions that modify the control flow of the program. This set potentially contains both conditional and unconditional jumps, but we track only conditional ones. Specifically, we record the branch taken at each conditional jump, and symbolically record it as an (in)equality. For example, if the branch `beq $1, $2, foolabel` is not taken, then we will add $r_1 \neq r_2$ to our trace.

One additional point of note: the program counter (`pc`) is not symbolically tracked. This means Tamarin cannot reason about unconditional jumps, so only a single path is explored for the program in Figure 8. There, Tamarin will execute P with the initial inputs (a hard-coded constant) and error out, because the jump will lead to an invalid instruction. Tamarin will miss the fact that $1 and $2 can be given values such that we could jump to either of the labels, leading to a successful execution.

```
# P
  add $4, $1, $2
  jr $4
good:
  add $3, $1, $2
  jr $31 # $31 contains the termination pc
bad:
  add $3, $1, $1
  jr $31
```

Fig. 8. Not tracking the `pc` leads to under-approximations

Since the `pc` is not tracked, whenever it is used in another instruction we need to substitute it by its concrete value. This technique is called concretization [David et al., 2016]. For example, the load immediate and skip instruction has the following semantics:

`lis $d` $\quad d \leftarrow Mem[pc]; pc \leftarrow pc + 4$

Instead of the (precise) interpretation above, we use concretization to generate the (under-approximating) symbolic instruction $d \leftarrow v$, where v is the value at the address following the `lis` instruction.

4.2 Transformations

The Trace module also exposes just a single function:

```
def transform(trace: Trace, depth: Int): Trace
```

transform takes as input a trace that was produced by CPU and a depth parameter (explained below), and modifies the input trace so that it can be later converted into a logical formula. The depth parameter limits the number of path conditions in the outputted trace: this is so we can bound the depth of our DFS as we explore new paths (see Section 4.4 for more details). In effect, we can think of traces as the intermediate representation (IR) for queries to the SMT solver. The Trace module can be then thought of as lowering the semantic complexity of traces.

Internally, Trace consists of multiple phases, each of type `Trace => Trace`, which are sequentially applied to the input. They are described below.

Desugaring The desugaring phase removes "complicated" instructions by replacing them with simpler ones. Figure 9 summarizes some of the transformations.

Input	**Output**
$Jalr(concretePC)$	$Add(\$31, concretePC)$
$Mult(s,t)$	$Mult64(tmp,s,t); Low32(lo,tmp); High32(hi,tmp)$
$Div(s,t)$	$Quot(lo,s,t); Rem(hi,s,t)$
$Mflo(d)$	$Add(d,lo,0)$

Fig. 9. Desugared instructions

A couple of points of interest:

- $31 holds by convention the return address of the current procedure. Since the pc is not tracked, its concretized value is used.
- Notice how some instructions (e.g. $Mult$) are desugared into multiple instructions: this is because they in fact have more than one side effect in the CPU state.
- While desugaring some instructions, we introduce "helper" instructions like $Mult64$ and $Quot$ that are not part of the MIPS instruction set. These instructions help communicate the intended semantics to the SMT solver. For example, later on we will see that the contents of registers are represented with 32-bit vectors, but multiplication of two 32-bit integers can take up to 64 bits of storage, so we need a way to let the solver know that it should upcast the product of two registers (so we can later decompose it into the low and high 32-bits): the $Mult64$ instruction accomplishes this.

Simplification The simplification phase removes trivial path conditions, like `beq 0, 0, foolabel`, which might be common (the specific `beq` example is a common idiom for jumping to a loop header) but do not need to be considered by the SMT solver.

Trimming The trimming phase just shortens the trace so that it contains at most depth (an argument to Trace) path conditions. This is so we can do a bounded DFS (again, see Section 4.4) to limit the search space.

SSA Conversion The SSA phase converts traces into static single assignment (SSA) form [Cytron et al., 1991]. SSA form is crucial to be able to transform a trace into the corresponding logical formula. Consider the example in Figure 10, which shows a small trace together with incorrect and correct translations.

The incorrect translation represents assignment through equality. This is intuitive, but misguided, because assignment mutates state, but equality does not. For example, suppose we append to our trace the path condition $\$3 = 9 \wedge \$1 = 3$. This gets translated to the equality $z = 9 \wedge x = 3$. But the equalities in the incorrect translation imply that $y = 0$ (because $x = x - y$) and so $z = x = y$. The path condition is then declared as unsatisfiable, but this is clearly wrong, because $\$1 = 6 \wedge \$2 = 3$ is a solution.

What went wrong, and how do we fix it? As we pointed, assignment mutates the value of registers, so we need to somehow encode that the "$1" in the last *Add* instruction is "not the same" as the one in the first *Add*. This behaviour is precisely captured by SSA form, where each variable is assigned to exactly once. This means that two reads of the same register that are separated by a write to the same register will be encoded as different variables. The correct translation in Figure 10 uses subscripts to refer to the "versions" of each variable after writes. If we add the same path condition as before, we can see that it gets translated as $z_1 = 9 \wedge x_2 = 3$, which is now satisfiable because $x_2 = x_1 - y_1$ does not imply that $x_1 = y_1$.

Trace	**Incorrect**	**Correct**
$Add(\$3, \$1, \$2)$	$z = x + y$	$z_1 = x_1 + y_1$
$Sub(\$1, \$1, \$2)$	$x = x - y$	$x_2 = x_1 - y_1$
$Add(\$2, \$1, \$2)$	$y = x + y$	$y_2 = x_2 + y_1$

Fig. 10. A trace together with an incorrect translation to a logical formula and a correct translation using SSA form

The algorithms for efficiently converting code into SSA form are sophisticated [Cytron et al., 1991], requiring the calculation of so-called dominators and ϕ-functions. However, we are only interested in converting traces, which do not contain any jumps. In this case, a simple linear-time pass over the trace suffices for converting to SSA. The algorithm is shown in Figure 11.

4.3 Queries

The Query module is responsible for interfacing with the Z3 solver to determine the satisfiability of path constraints, leading to unexplored program paths.

```
function ssaConvert(trace)
    trace′ ← ∅
    ∀x.last(x) ← x1
    for all instr ∈ trace do
        if instr = Add(d, s, t) then
            s′ ← last(s)
            t′ ← last(t)
            di ← last(d)
            last(d) ← di+1
            instr′ ← Add(di+1, s′, t′)
            append(trace′, instr′)
        else ...                                          ▷ Other cases
        end if
    end for
    return trace′
end function
```

Fig. 11. SSA conversion of traces

The API for the module is the function

```
def solve(trace: Trace): Option[Soln]
```

The input to solve is a trace that has been processed by Trace, likely containing a recently-negated path condition (negated by the Concolic module from Section 4.4). solve's task is to convert the trace into an equivalent logical formula, hand it to Z3, and then return the solution found by the solver.

A Soln is just a `Seq[RegVal]` (solve returns an Option[Soln] in case the formula is unsatisfiable), and a RegVal is an algebraic datatype of the form

```
case object Unbound extends RegVal
case class Fixed(v: Long) extends RegVal
```

A RegVal represents the value of a register in the model returned by the solver. Unbound represents the case when the solver does not constrain a register in its solution. By contrast, Fixed is used when the solver requires a specific value.

Translation Figure 12 shows an example of how a program trace can be converted into a logical formula understood by the solver. In this case, the program has a single conditional branch, leading to one path condition. Presumably, we have already explored (perhaps from the initial run with random inputs) what happens when the branch is taken (that is $4 = $5 and so we skip the last addition). Now we are interested in exploring the case where the branch is not taken: for that, we need the path condition $4 ≠ $5 at the end of the trace.

The third column in Figure 12 shows the logical formula that is produced by the Query module. The formula is satisfiable iff the path condition $4 ≠ $5 can evaluate to true for certain values of $1 and $2. In Figure 12, we have used the SMT-LIB [Barrett et al., 2010] representation of the query, which is a textual representation with a Lisp-like syntax. Tamarin uses Z3's Java API, for efficiency.

Every register in the trace has a corresponding "constant" in the formula $(r_1 \dots r_6)$. The constants have type "32-bit bitvector", to encode that registers are 32-bit inte-

program:

```
  add $3, $1, $2
  slt $4, $1, $2
  lis $5
  1
  beq $4, $5, skip
  add $6, $3, $1
skip:
```

trace:

```
  add $3, $1, $2
  slt $4, $1, $2
  add $5, $1, $0
  $4 != $5
```

SMT-LIB:

```
(declare-const r1 (_ BitVec 32))
(declare-const r2 (_ BitVec 32))
(declare-const r3 (_ BitVec 32))
(declare-const r4 (_ BitVec 32))
(declare-const r5 (_ BitVec 32))

(assert (= r0 (_ bv0 32)))
(assert (= r3 (bvadd r1 r2)))
(assert
  (= r4 (ite (bvslt r1 r2)
    (_ bv1 32)
    (_ bv0 32))))
(assert (= r5 (_ bv1 32)))
(assert (not (= r4 r5)))

(check-sat)
(get-model)
```

Fig. 12. A sample program, a trace in it, and the trace's representation in SMT-LIB notation

gers. Consequently, arithmetic operations on registers are encoded as operations on bitvectors (e.g. bvadd, bvslt).

Some instructions like `slt` have domain-specific semantics, so their translations are slightly more complicated: `slt` specifically uses SMT-LIB's ite (if-then-else) construct.

There is no mutation in the formula, but that is ok because of our conversion to SSA from Section 4.2. Instead of mutation, relationships between constants are encoded using assertions. In general, we have one assertion per instruction in the trace.

Once all constant declarations and assertions have been specified, we can query Z3 to check the satisfiability of the formula via (check-sat). If the formula is satisfiable, we can also request the satisfying model that Z3 found, with get-model. In this case, Z3 returns

```
(model (define-fun r1 () (_ BitVec 32) #x80000000)
       (define-fun r2 () (_ BitVec 32) #x80000000)
           ...)
```

Which indeed is a solution (albeit not one a human would have picked), because it makes `slt $4, $1, $2` assign 0 to $4, which skips the branch.

Memory Representation In keeping with registers being represented as 32-bit bitvectors, Tamarin represents memory itself as an array of bitvectors. Below we show the translations of the `sw` and `lw` instructions:

```
lw $t, i, $s        (assert (= r_t (select mem_last (bvadd i r_s))))
sw $t, i, $s        (assert (= mem_k+1 (store mem_k (bvadd i r_s) r_t))
```

Notice how memory is also immutable: every store (`sw`) operation returns a new memory constant (an array), and every select (`lw`) uses the latest memory constant .

4.4 Concolic Execution Redux

As mentioned before, the Concolic module implements the concolic execution engine and orchestrates the interactions between all modules. We already presented the general structure in Figure 3, but below we expand on some additional points.

Alternation The main difference between Tamarin and a traditional concolic execution engine is that Tamarin needs to maintain state for the two programs it is comparing, and opposed to just one. Therefore, we represent the engine state with a tuple $(trace_1, trace_2, turn)$ of the last-executed trace for each program, together with a pointer to the last-run program. At every iteration, we use $turn$ to choose the program that is next in line for execution, and use the corresponding $trace_i$ to identify the last path-condition (and the corresponding inputs) that has not been previously negated. The programs are run on the new inputs, their traces recorded, and a new state $(trace'_1, trace'_2, turn')$ generated.

Bounded DFS As in the original concolic testing tool, CUTE [Sen et al., 2005], Tamarin explores program paths using a bounded depth-first search. To guarantee termination, Tamarin trims CPU traces so that they contain at most depth path conditions (later path conditions are simply ignored). The current depth is set at 50, but is configurable.

Comparing Results When are the results of the two programs consider contradictory? Only when both programs terminate with different values in \$3, or when one program fails while the other succeeds. In particular, non-termination is treated conservatively and no inferences are derived from it (this could be modified soundly if one of the two programs is given a "priviledged" status by considering it the specification). The full rules are those in Section 2.

Soundness and Completeness As we saw in Lemma 1, Tamarin is sound, but not complete. There are multiple sources of incompleteness: not all paths are explored (because of the depth parameter), termination is ensured via the fuel, and part of the program state is simply not tracked at all, leading to under-approximation.

Efficiency We have not done an formal complexity analysis of the algorithm implemented by Tamarin. In any case, as with other concolic execution tools, there is a risk of combinatorial path explosion, which can be traded away in exchange for a loss in precision via the depth parameter. A similar tradeoff exists with the fuel parameter. The theories used by Tamarin via Z3 are quanitifier-free bitvectors and arrays, including multiplication, which is potentially problematic. If further testing revealed an impact to performance, we would look into concretization strategies to handle the multiplication case.

5 Evaluation

To evaluate the correctness of Tamarin, we hand-wrote a set of assembly programs (program pairs, to be more precise) that exercise different functionality in the tool. The test programs are summarized in Figure 13.

Program	Tested Property
stack	Can reason about pushs and pops to the stack
fun	Finds counterexamples across function calls
while	Able to reason about loops that iterate less than depth times
infinite	Treats infinite loops conservatively
div0	Can handle CPU exceptions
nested	Reasons about nested conditional statements

Fig. 13. Test programs for Tamarin

The tests we have to date focus on correctness (and, indirectly, measure efficiency), but they are all small and simple programs. To evaluate whether Tamarin is of practical use, we plan to collect student-written compilers for an undergraduate course at the University of Waterloo. We can then feed these submitted compilers sample programs written in a Scala-like language. We can compare the MIPS code generated by the student's compilers to that of the reference implementation, using Tamarin. Finally, we will compare Tamarin's results with the current black-box testing approach used in the course, and investigate whether Tamarin provides better accuracy.

6 Related Work

We now survey some of the existing literature on program equivalence that is relevant to the project. In general, many tools have been built for checking program equivalence, differing on the language they target (high level vs assembly), their level of generality (one-off tools vs frameworks or even intermediate languages that serve as the backend for multiple tools), the language features they support (loops vs loop unrolling) and their soundness and completeness guarantees (concolic testing based tools vs complete exploration of a bounded search space). However, we were not able to find a tool that both does program equivalence and works with raw assembly programs.

The two ecosystems of tools most relevant to our work are KLEE and Boogie.

KLEE [Cadar et al., 2008] introduced KLEE, which is now a popular backend for program verification tasks. It implements a symbolic VM for LLVM bitcode. However, unlike Tamarin, the input to KLEE is at the C level. [Ramos and Engler, 2011] build UC-KLEE on top of KLEE. Given two C functions, UC-KLEE checks whether they are equivalent (up to a fixed input size of 8 bytes). Their notion of equivalence considers not only function return values, but also memory locations reachable from them. As far as we can tell, UC-KLEE was never released publicly.

Boogie [Barnett et al., 2005] present Boogie, an intermediate verification language that can be targeted as an IR for program verification tasks. [Lahiri et al., 2012] built SymDiff on top of Boogie to test for program equivalence. However, even though Boogie can encode MIPS, SymDiff requires that procedures in the two compared programs be given in pairs via a pre-established correspondence. This is so that Boogie can reason about one procedure at a time, making conservative assumptions about the state of the other procedures. This makes it unclear whether SymDiff could be used to verify equivalence of arbitrary MIPS programs whose structures we do not know a-priori. [Hawblitzel et al., 2013] verify compiler correctness by checking program equivalence of emitted assembly code. They use x86, Boogie, and SymDiff.

Other related work [Person et al., 2011] combine static analysis and symbolic execution for program equivalence. [Egele et al., 2014] use *Blanket Execution* to identify portions of program binaries that are "'similar', based on randomized testing and having similar side-effects. [Partush and Yahav, 2013] use abstract interpretation to prove program equivalence for numerical programs. [Yang et al., 2014] show how verify that manually-annotated program properties continue to hold as a program evolves. [Necula, 2000] verifies equivalence of IRs before and after compiler passes. [Francesco et al., 2014] present GreASE, which focuses on non-equivalence checking. [Sharma et al., 2013] are able to check equivalence of x86 loops, unlike most of the other tools, which need to unroll loops.

7 Future Work

Tamarin is still very much a work-in-progress. Below we list some of the outstanding work.

Data Structure Generation The CUTE tool [Sen et al., 2005] is able to generate not only numeric inputs, but also C-like `structs` using a somewhat inductive approach: to generate a `struct`, first generate `null`, then generate an instance of the `struct` where all fields are `null`, and then iterate the construction. This is harder to do in Tamarin, because it is working at the assembly level. Unlike in C, where we have `struct` definitions to guide the "shapes" we need to generate, Tamarin has no type-level information to guide the creation of data structures. One option is to specify such shape with metadata that is given to Tamarin as input together with the two programs.

Restarts Because we do not precisely track the semantics of the executed MIPS program (for example, we ignore the `pc`), it is possible that we solve a set of path constraints, but the resulting input does not lead the MIPS program along the executed constraints. In these cases, Tamarin currently stops evaluating the "misdirected" program (we will however continue to concolically execute the second program). Another approach, also used in CUTE, is to restart the engine with random inputs. We do not currently know how common restarts are, but they might be worth implementing for more complicated programs.

Experiments As mentioned in Section 5, we would like to run Tamarin with compiler-generated MIPS programs, to test scalability and real-world use. This would be easier to do if we could generate data structures, since many programs take more two integers as input.

8 Conclusions

Program equivalence is a hard problem. Equivalence of assembly language programs is arguably even harder, because it needs to handle the unstructured nature of assembly without type or grammar-level information.

Surprisingly, there does not seem to be a program equivalence tool that works at the assembly level (for arbitrary programs). Tamarin is one step in this direction.
